NCP1573

Low Voltage Synchronous Buck Controller

The NCP1573 is a low voltage buck controller. It provides the control for a DC-DC power solution producing an output voltage as low as 0.980 V over a wide current range. The NCP1573-based solution is powered from 12 V with the output derived from a 2-7 V supply. It contains all required circuitry for a synchronous NFET buck regulator using the V²™ control method to achieve the fastest possible transient response and best overall regulation. NCP1573 operates at a fixed internal 200 kHz frequency and is packaged in an SO-8.

This device provides Power Good with delay and built-in adaptive non-overlap.

Features

- 0.980 V $\pm$ 1.0% Reference Voltage
- V² Control Topology
- 200 ns Transient Response
- Power Good
- Programmable Power Good Delay
- 40 ns Gate Rise and Fall Times (3.3 nF Load)
- Adaptive FET Non-Overlap Time
- Fixed 200 kHz Oscillator Frequency
- On/Off Control Through Use of the COMP Pin
- Overvoltage Protection through Synchronous MOSFETs
- Synchronous N-Channel Buck Design
- Dual Supply, 12 V Control, 2-7 V Power Source

APPLICATION INFORMATION

THEORY OF OPERATION

The NCP1573 is a simple, synchronous, fixed-frequency, low-voltage buck controller using the V^2 control method. It provides a programmable-delay Power Good function to indicate when the output voltage is out of regulation.

 V^2 Control Method

The V^2 control method uses a ramp signal generated by the ESR of the output capacitors. This ramp is proportional to the AC current through the main inductor and is offset by the DC output voltage. This control scheme inherently compensates for variation in either line or load conditions, since the ramp signal is generated from the output voltage itself. The V^2 method differs from traditional techniques such as voltage mode control, which generates an artificial ramp, and current mode control, which generates a ramp using the inductor current.

Figure 19. V^2 Control with Slope Compensation

The V^2 control method is illustrated in Figure 19. The output voltage generates both the error signal and the ramp signal. Since the ramp signal is simply the output voltage, it is affected by any change in the output, regardless of the origin of that change. The ramp signal also contains the DC portion of the output voltage, allowing the control circuit to drive the main switch from 0% to 100% duty cycle as required.

Figure 20. Idealized Waveforms

A variation in line voltage changes the current ramp in the inductor, which causes the V^2 control scheme to compensate the duty cycle. Since any variation in inductor current modifies the ramp signal, as in current mode control, the V^2 control scheme offers the same advantages in line transient response.

A variation in load current will affect the output voltage, modifying the ramp signal. A load step immediately changes the state of the comparator output, which controls the main switch. The comparator response time and the transition speed of the main switch determine the load transient response. Unlike traditional control methods, the reaction time to the output load step is not related to the crossover frequency of the error signal loop.

The error signal loop can have a low crossover frequency, since the transient response is handled by the ramp signal loop. The main purpose of this 'slow' feedback loop is to provide DC accuracy. Noise immunity is significantly improved, since the error amplifier bandwidth can be rolled off at a low frequency. Enhanced noise immunity improves remote sensing of the output voltage, since the noise associated with long feedback traces can be effectively filtered.

Line and load regulation are drastically improved because there are two independent control loops. A voltage mode controller relies on the change in the error signal to compensate for a deviation in either line or load voltage. This change in the error signal causes the output voltage to change corresponding to the gain of the error amplifier, which is normally specified as line and load regulation. A current mode controller maintains a fixed error signal during line transients, since the slope of the ramp signal changes in this case. However, regulation of load transients still requires a change in the error signal. The V^2 method of control maintains a fixed error signal for both line and load variation, since the ramp signal is affected by both line and load.

The stringent load transient requirements of modern microprocessors require the output capacitors to have very low ESR. The resulting shallow slope in the output ripple can lead to pulse width jitter and variation caused by both random and synchronous noise. A ramp waveform generated in the oscillator is added to the ramp signal from the output voltage

to provide the proper voltage ramp at the beginning of each switching cycle. This slope compensation increases the noise immunity, particularly at duty cycles above 50%.

Start Up

The NCP1573 features a programmable Soft Start function, which is implemented through the error amplifier and the external compensation capacitor. This feature prevents stress to the power components and limits output voltage overshoot during start-up. As power is applied to the regulator, the compensation capacitor connected to the COMP pin is charged by a 30 μ A current source. When the capacitor voltage exceeds the 0.525 V offset of the PWM comparator, the PWM control loop will allow switching to occur. The upper gate driver GATE(H) is activated, turning on the upper MOSFET. The current ramps up through the main inductor and linearly powers the output capacitors and load. When the regulator output voltage exceeds the COMP pin voltage minus the 0.525 V PWM comparator offset threshold and the artificial ramp, the PWM comparator terminates the initial pulse.

Normal Operation

During normal operation, the duty cycle of the gate drivers remains approximately constant as the V^2 control loop maintains the regulated output voltage under steady state conditions. Variations in supply line or output load conditions will result in changes in duty cycle to maintain regulation.

Input Supplies

The NCP1573 can be used in applications where a 12 V supply is available along with a lower voltage supply. Often the lower voltage supply is 5 V, but it can be any voltage less than the 12 V supply minus the required gate drive voltage of the top MOSFET. The greater the difference between the two voltages, the better the efficiency due to increasing V_{GS} available to turn on the upper MOSFET. In order to maintain power supply stability, the lower supply voltage should be at least 1.5 times the desired voltage.

A lower supply voltage between 2–7 V is recommended.

Gate Charge Effect on Switching Times

When using the onboard gate drivers, the gate charge has an important effect on the switching times of the FETs. A finite amount of time is required to charge the effective capacitor seen at the gate of the FET. Therefore, the rise and fall times rise linearly with increased capacitive loading.

Transient Response

The 200 ns reaction time of the control loop provides fast transient response to any variations in input voltage and output current. Pulse-by-pulse adjustment of duty cycle is provided to quickly ramp the inductor current to the required level. Since the inductor current cannot be changed instantaneously, regulation is maintained by the output capacitors during the time required to slew the inductor current. For better transient response, several high frequency and bulk output capacitors are usually used.

Figure 21. PWRGD Assertion

Overvoltage Protection

Overvoltage protection is provided as a result of the normal operation of the V^2 control method and requires no additional external components. The control loop responds to an overvoltage condition within 200 ns, turning off the upper MOSFET and disconnecting the regulator from its input voltage. This results in a crowbar action to clamp the output voltage, preventing damage to the load. The regulator remains in this state until the overvoltage condition ceases.

Power Good

The PWRGD pin is asserted when the output voltage is within regulation limits. Sensing for the PWRGD pin is achieved through the V_{FB} pin. When the output voltage is rising, PWRGD goes high at 90% of the designed output voltage. When the output voltage is falling, PWRGD goes low at 70% of the designed output voltage. PWRGD is an open-collector output and should be externally pulled to logic high through a resistor to limit current to no more than 20 mA. Figure 21 shows the hysteretic nature of the PWRGD pin's operation.

CONVERTER DESIGN

Selection of the Output Capacitors

These components must be selected and placed carefully to yield optimal results. Capacitors should be chosen to provide acceptable ripple on the regulator output voltage. Key specifications for output capacitors are their ESR (Equivalent Series Resistance), and ESL (Equivalent Series Inductance). For best transient response, a combination of low value/high frequency and bulk capacitors placed close to the load will be required.

In order to determine the number of output capacitors the maximum voltage transient allowed during load transitions has to be specified. The output capacitors must hold the output voltage within these limits since the inductor current can not change with the required slew rate. The output capacitors must therefore have a very low ESL and ESR.

The voltage change during the load current transient is:

$$\Delta V_{OUT} = \Delta I_{OUT} \times \left(\frac{ESL}{\Delta t} + ESR + \frac{t_{TR}}{C_{OUT}} \right)$$

where:

$\Delta I_{OUT} / \Delta t$ = load current slew rate;

ΔI_{OUT} = load transient;

Δt = load transient duration time;

ESL = Maximum allowable ESL including capacitors, circuit traces, and vias;

ESR = Maximum allowable ESR including capacitors and circuit traces;

t_{TR} = output voltage transient response time.

The designer has to independently assign values for the change in output voltage due to ESR, ESL, and output capacitor discharging or charging. Empirical data indicates that most of the output voltage change (droop or spike depending on the load current transition) results from the total output capacitor ESR.

The maximum allowable ESR can then be determined according to the formula:

$$ESR_{MAX} = \frac{\Delta V_{ESR}}{\Delta I_{OUT}}$$

where:

ΔV_{ESR} = change in output voltage due to ESR (assigned by the designer)

Once the maximum allowable ESR is determined, the number of output capacitors can be found by using the formula:

$$\text{Number of capacitors} = \frac{ESR_{CAP}}{ESR_{MAX}}$$

where:

ESR_{CAP} = maximum ESR per capacitor (specified in manufacturer's data sheet).

ESR_{MAX} = maximum allowable ESR.

The actual output voltage deviation due to ESR can then be verified and compared to the value assigned by the designer:

$$\Delta V_{ESR} = \Delta I_{OUT} \times ESR_{MAX}$$

Similarly, the maximum allowable ESL is calculated from the following formula:

$$ESL_{MAX} = \frac{\Delta V_{ESL} \times \Delta t}{\Delta I}$$

Selection of the Input Inductor

A common requirement is that the buck controller must not disturb the input voltage. One method of achieving this is by using an input inductor and a bypass capacitor. The input inductor isolates the supply from the noise generated in the switching portion of the buck regulator and also limits the inrush current into the input capacitors upon power up. The inductor's limiting effect on the input current slew rate becomes increasingly beneficial during load transients. The worst case is when the load changes from no load to full load (load step), a condition under which the highest voltage change across the input capacitors is also seen by the input inductor. The inductor successfully blocks the ripple current while placing the transient current requirements on the input

bypass capacitor bank, which has to initially support the sudden load change.

The minimum inductance value for the input inductor is therefore:

$$L_{IN} = \frac{\Delta V}{(di/dt)_{MAX}}$$

where:

L_{IN} = input inductor value;

ΔV = voltage seen by the input inductor during a full load swing;

$(di/dt)_{MAX}$ = maximum allowable input current slew rate.

The designer must select the LC filter pole frequency so that at least 40 dB attenuation is obtained at the regulator switching frequency. The LC filter is a double-pole network with a slope of -2.0, a roll-off rate of -40 dB/dec, and a corner frequency:

$$f_C = \frac{1}{2\pi \times \sqrt{LC}}$$

where:

L = input inductor;

C = input capacitor(s).

Selection of the Output Inductor

There are many factors to consider when choosing the output inductor. Maximum load current, core and winding losses, ripple current, short circuit current, saturation characteristics, component height and cost are all variables that the designer should consider. However, the most important consideration may be the effect inductor value has on transient response.

The amount of overshoot or undershoot exhibited during a current transient is defined as the product of the current step and the output filter capacitor ESR. Choosing the inductor value appropriately can minimize the amount of energy that must be transferred from the inductor to the capacitor or vice-versa. In the subsequent paragraphs, we will determine the minimum value of inductance required for our system and consider the trade-off of ripple current vs. transient response.

In order to choose the minimum value of inductance, input voltage, output voltage and output current must be known. Most computer applications use reasonably well regulated bulk power supplies so that, while the equations below specify $V_{IN(MAX)}$ or $V_{IN(MIN)}$, it is possible to use the nominal value of V_{IN} in these calculations with little error.

Current in the inductor while operating in the continuous current mode is defined as the load current plus ripple current.

$$I_L = I_{LOAD} + I_{RIPPLE}$$

The ripple current waveform is triangular, and the current is a function of voltage across the inductor, switch FET on-time and the inductor value. FET on-time can be defined as the product of duty cycle and switch frequency, and duty cycle can be defined as a ratio of V_{OUT} to V_{IN} . Thus,

$$I_{\text{RIPPLE}} = \frac{(V_{\text{IN}} - V_{\text{OUT}})V_{\text{OUT}}}{(f_{\text{OSC}})(L)(V_{\text{IN}})}$$

Peak inductor current is defined as the load current plus half of the peak current. Peak current must be less than the maximum rated FET switch current, and must also be less than the inductor saturation current. Thus, the maximum output current can be defined as:

$$I_{\text{OUT(MAX)}} = I_{\text{SWITCH(MAX)}} - \frac{(V_{\text{IN(MAX)}} - V_{\text{OUT}})V_{\text{OUT}}}{(2)(f_{\text{OSC}})(L)(V_{\text{IN(MAX)}})}$$

Since the maximum output current must be less than the maximum switch current, the minimum inductance required can be determined.

$$L_{\text{(MIN)}} = \frac{(V_{\text{IN(MIN)}} - V_{\text{OUT}})V_{\text{OUT}}}{(f_{\text{OSC}})(I_{\text{SWITCH(MAX)}})(V_{\text{IN(MIN)}})}$$

This equation identifies the value of inductor that will provide the full rated switch current as inductor ripple current, and will usually result in inefficient system operation. The system will sink current away from the load during some portion of the duty cycle unless load current is greater than half of the rated switch current. Some value larger than the minimum inductance must be used to ensure the converter does not sink current. Choosing larger values of inductor will reduce the ripple current, and inductor value can be designed to accommodate a particular value of ripple current by replacing $I_{\text{SWITCH(MAX)}}$ with a desired value of I_{RIPPLE} :

$$L_{\text{(RIPPLE)}} = \frac{(V_{\text{IN(MIN)}} - V_{\text{OUT}})V_{\text{OUT}}}{(f_{\text{OSC}})(I_{\text{RIPPLE}})(V_{\text{IN(MIN)}})}$$

However, reducing the ripple current will cause transient response times to increase. The response times for both increasing and decreasing current steps are shown below.

$$T_{\text{RESPONSE(INCREASING)}} = \frac{(L)(\Delta I_{\text{OUT}})}{(V_{\text{IN}} - V_{\text{OUT}})}$$

$$T_{\text{RESPONSE(DECREASING)}} = \frac{(L)(\Delta I_{\text{OUT}})}{(V_{\text{OUT}})}$$

Inductor value selection also depends on how much output ripple voltage the system can tolerate. Output ripple voltage is defined as the product of the output ripple current and the output filter capacitor ESR.

Thus, output ripple voltage can be calculated as:

$$V_{\text{RIPPLE}} = (ESR_C)(I_{\text{RIPPLE}}) = \frac{(ESR_C)(V_{\text{IN}} - V_{\text{OUT}})V_{\text{OUT}}}{(f_{\text{OSC}})(L)(V_{\text{IN}})}$$

Finally, we should consider power dissipation in the output inductors. Power dissipation is proportional to the square of inductor current:

$$P_D = (I^2)(ESR_L)$$

The temperature rise of the inductor relative to the air surrounding it is defined as the product of power dissipation and thermal resistance to ambient:

$$\Delta T(\text{inductor}) = (R_a)(P_D)$$

R_a for an inductor designed to conduct 20 A to 30 A is approximately 45°C/W. The inductor temperature is given as:

$$T(\text{inductor}) = \Delta T(\text{inductor}) + T_{\text{ambient}}$$

V_{CC} Bypass Filtering

A small RC filter should be added between module V_{CC} and the V_{CC} input to the IC. A 10 Ω resistor and a 0.47 μF capacitor should be sufficient to ensure the controller IC does not operate erratically due to injected noise, and will also supply reserve charge for the onboard gate drivers.

Input Filter Capacitors

The input filter capacitors provide a charge reservoir that minimizes supply voltage variations due to changes in current flowing through the switch FETs. These capacitors must be chosen primarily for ripple current rating.

Figure 22.

Consider the schematic shown in Figure 22. The average current flowing in the input inductor L_{IN} for any given output current is:

$$I_{\text{IN(AVE)}} = I_{\text{OUT}} \times \frac{V_{\text{OUT}}}{V_{\text{IN}}}$$

Input capacitor current is positive into the capacitor when the switch FETs are off, and negative out of the capacitor when the switch FETs are on. When the switches are off, $I_{\text{IN(AVE)}}$ flows into the capacitor. When the switches are on, capacitor current is equal to the per-phase output current minus $I_{\text{IN(AVE)}}$. If we ignore the small current variation due to the output ripple current, we can approximate the input capacitor current waveform as a square wave. We can then calculate the RMS input capacitor ripple current:

$$I_{\text{RMS(CIN)}} = \sqrt{I_{\text{IN(AVE)}}^2 + \frac{V_{\text{OUT}}}{V_{\text{IN}}} \times [(I_{\text{OUT per phase}} - I_{\text{IN(AVE)}})^2 - I_{\text{IN(AVE)}}^2]}$$

The input capacitance must be designed to conduct the worst case input ripple current. This will require several capacitors in parallel. In addition to the worst case current, attention must be paid to the capacitor manufacturer's derating for operation over temperature.

As an example, let us define the input capacitance for a 5 V to 3.3 V conversion at 10 A at an ambient temperature of 60°C. Efficiency of 80% is assumed. Average input current in the input filter inductor is:

$$I_{IN(AVE)} = (10 \text{ A})(3.3 \text{ V}/5 \text{ V}) = 6.6 \text{ A}$$

Input capacitor RMS ripple current is then

$$I_{IN(RMS)} = \sqrt{6.6^2 + \frac{3.3 \text{ V}}{5 \text{ V}} \times [(10 \text{ A} - 6.6 \text{ A})^2 - 6.6 \text{ A}^2]} \\ = 4.74 \text{ A}$$

If we consider a Rubycon MBZ series capacitor, the ripple current rating for a 6.3 V, 1800 nF capacitor is 2000 mA at 100 kHz and 105°C. We determine the number of input capacitors by dividing the ripple current by the per-capacitor current rating:

$$\text{Number of capacitors} = 4.74 \text{ A}/2.0 \text{ A} = 2.3$$

A total of at least 3 capacitors in parallel must be used to meet the input capacitor ripple current requirements.

Output Switch FETs

Output switch FETs must be chosen carefully, since their properties vary widely from manufacturer to manufacturer. The NCP1573 system is designed assuming that n-channel FETs will be used. The FET characteristics of most concern are the gate charge/gate-source threshold voltage, gate capacitance, on-resistance, current rating and the thermal capability of the package.

The onboard FET driver has a limited drive capability. If the switch FET has a high gate charge, the amount of time the FET stays in its ohmic region during the turn-on and turn-off transitions is larger than that of a low gate charge FET, with the result that the high gate charge FET will consume more power. Similarly, a low on-resistance FET will dissipate less power than will a higher on-resistance FET at a given current. Thus, low gate charge and low $R_{DS(ON)}$ will result in higher efficiency and will reduce generated heat.

It can be advantageous to use multiple switch FETs to reduce power consumption. By placing a number of FETs in parallel, the effective $R_{DS(ON)}$ is reduced, thus reducing the ohmic power loss. However, placing FETs in parallel increases the gate capacitance so that switching losses increase. As long as adding another parallel FET reduces the ohmic power loss more than the switching losses increase, there is some advantage to doing so. However, at some point the law of diminishing returns will take hold, and a marginal increase in efficiency may not be worth the board area required to add the extra FET. Additionally, as more FETs are used, the limited drive capability of the FET driver will have to charge a larger gate capacitance, resulting in increased gate voltage rise and fall times. This will affect the amount of time the FET operates in its ohmic region and will increase power dissipation.

The following equations can be used to calculate power dissipation in the switch FETs.

For ohmic power losses due to $R_{DS(ON)}$:

$$P_{ON(TOP)} = \frac{(R_{DS(ON)}(TOP))(I_{RMS(TOP)})^2}{(\text{number of topside FETs})}$$

$$P_{ON(BOTTOM)} = \frac{(R_{DS(ON)}(BOTTOM))(I_{RMS(BOTTOM)})^2}{(\text{number of bottom-side FETs})}$$

where:

n = number of phases.

Note that $R_{DS(ON)}$ increases with temperature. It is good practice to use the value of $R_{DS(ON)}$ at the FET's maximum junction temperature in the calculations shown above.

$$I_{RMS(TOP)} = \sqrt{I_{PK}^2 - (I_{PK})(I_{RIPPLE}) + \frac{D}{3} I_{RIPPLE}^2}$$

$$I_{RMS(BOTTOM)} = \sqrt{I_{PK}^2 - (I_{PK})(I_{RIPPLE}) + \frac{(1-D)}{3} I_{RIPPLE}^2}$$

$$I_{\text{RIPPLE}} = \frac{(V_{\text{IN}} - V_{\text{OUT}})(V_{\text{OUT}})}{(f_{\text{OSC}})(L)(V_{\text{IN}})}$$

$$I_{\text{PEAK}} = I_{\text{LOAD}} + \frac{I_{\text{RIPPLE}}}{2} = \frac{I_{\text{OUT}}}{3} + \frac{I_{\text{RIPPLE}}}{2}$$

where:

D = Duty cycle.

For switching power losses:

$$P_D = nCV^2(f_{\text{OSC}})$$

where:

n = number of switch FETs (either top or bottom),

C = FET gate capacitance,

V = maximum gate drive voltage (usually V_{CC}),

f_{OSC} = switching frequency.

System Considerations for the NCP1573

The NCP1573 controller is optimized for converter designs where the power supply for the controller IC has very short turn-on and turn-off times. Such systems can be found providing power to graphics cards or memory where standby power is also provided. The key features of the NCP1573 are that undervoltage lockout and soft start resetting are not included. These features must be absent to allow the NCP1573 to interface in a glitch-free manner with back-up power supplies.

A schematic showing a possible system implementation using the NCP1573 is included in Figure 23. Note that an

external p-channel FET gates the 12 V supply to the IC. The signal also controls an alternate supply that drives a linear regulator. The linear regulator provides back-up power for the load during low-power operation.

In this case, the 12 V supply turn-on and turn-off is so fast that the controller does not charge or discharge the output capacitance significantly during the transition intervals. This minimizes glitching during the transitions. Also, note that a resistor divider and a diode connect the logic signal to the COMP pin of the NCP1573. The divider and diode network serve to hold the COMP voltage up when the IC is powered down. When the power management state changes and the IC powers back up, having the COMP voltage at its correct level further reduces glitching. The correct COMP level is determined to be the IC reference voltage (0.98 V) plus the channel start-up offset of the controller (0.525 V), plus about 10 mV to account for artificial ramp amplitude (total of 1.615 V). The divider voltage must be about 100 mV higher to allow for the diode forward voltage. Note that very little current is assumed to flow through the diode since only capacitor leakage current should be present.

There will always be some small voltage adjustment during transitions due to manufacturing tolerances. Having the COMP voltage slightly low will result in a temporary sag in the output voltage as the linear regulator turns off and the switching supply turns on. Similarly, a positive change in V_{OUT} will occur if the COMP voltage is slightly too high.

Figure 23.

Providing fast turn-on and turn-off edges to the IC power is very important in minimizing glitching because there is no undervoltage lockout circuitry. For example, if the switcher were powered up and regulating, and the supply began to decrease slowly, the GATE outputs of the IC would continue to switch until the driver circuitry ran out of headroom (when V_{CC} reaches approximately 5 V). When the drivers collapse, an on-chip resistor from the GATE pins to ground will bottom the external n-channel FETs and the switch

node becomes disconnected from the DC-DC converter. Until this happens, it is entirely possible that the bottom FET may have a large duty cycle and be trying to discharge the V_{OUT} capacitance. Additionally, as the bias circuitry in the IC collapses, the reference voltage to the error amplifier may change and result in false regulation. The circuit in Figure 23 will operate properly with turn-on and turn-off times on the order of 500 μ s or faster.

Layout Considerations

1. The fast response time of V^2 technology increases the IC's sensitivity to noise on the V_{FB} line. Fortunately, a simple RC filter, formed by the feedback network and a small capacitor (100 pF works well, shown below as C6) placed between V_{FB} and GND, filters out most noise and provides a system practically immune to jitter. This capacitor should be located as close as possible to the IC.
2. The COMP capacitor (shown below as C13) should be connected via its own path to the IC ground. The COMP capacitor is sensitive to the intermittent ground drops caused by switching currents. A separate ground path will reduce the potential for jitter.
3. The V_{CC} bypass capacitor (0.1 μ F or greater, shown below as C4) should be located as close as possible to the IC. This capacitor's connection to GND must be as short as possible. The 10 Ω resistor (shown below as R3) should be placed close to the V_{CC} pin.

4. The IC should not be placed in the path of switching currents. If a ground plane is used, care should be taken by the designer to ensure that the IC is not located over a ground or other current return path.
