USING THE IDT7052/7054 FOURPORT™ SRAMs IN DSP AND MATRIX PROCESSING APPLICATIONS

By Tao Lin, Julie Lin, and Yupling Chung

Introduction

Most digital signal processing (DSP) algorithms have inherent parallelism and may be pipelined. Usually, these algorithms are computation intensive. In real-time applications, multiprocessor or parallel distributed processor systems are commonly used to implement these DSP algorithms. In these types of systems it is necessary for different processors to randomly and independently access different locations at the same time in the same memory space. The IDT7052 (2Kx8) and IDT7054 (4Kx8) FourPort RAMs are powerful devices to efficiently and compactly implement the memory space in these applications. Moreover, the IDT7052 and IDT7054 can increase the speed of these types of systems since the FourPort SRAMs are as fast as conventional SRAMs and eliminate the complex external logic which introduces extra delay in these systems. In this application note, we will demonstrate some examples of using the IDT7052 to implement a high performance FFT processor and a matrix multiplication engine.

Using the IDT7052 in an FFT Processor

The IDT7052 FourPort SRAM can dramatically simplify the design of a high-speed pipelined FFT processor. The basic operation of any FFT algorithm is the butterfly computation:

$$G = C + e^{jW} \cdot D$$
$$H = C - e^{jW} \cdot D \tag{1-1}$$

$$G = C + e^{j\Omega} \cdot D$$
$$H = C - e^{j\Omega} \cdot D$$

where C, D, G, and H are complex numbers. Figure 1 shows the signal flow graph of the butterfly with one complex multiplication and two complex additions. Given $N = 2^L$ input data samples x(0), x(1)....., x(N-1), the FFT algorithm performs the Discrete Fourier Transform on the input data to obtain the output data X(0), X(1)....., X(N-1) in L stages of computation. Each stage consists of N/2 butterfly operations. There are two basic versions of the FFT algorithm: decimation-in-time (DIT) and decimation-in-frequency (DIF). Each version of the algorithm can be implemented using two schemes: not-in-place computation and in-place computation. A detailed discussion of the FFT algorithm and its implementations is given in Reference (1).

Figure 2 shows the signal flow graph of the not-in-place computation of the DIT FFT algorithm for N = 8(L=3). A close look at Figure 2 will reveal the major strength of the not-in-place scheme. The signal

$$W^k = e^{-j2\pi k/N}$$

paths from the initial inputs to the first intermediary step are repeated between the first and second intermediary steps, and again between the second and third. This means that three stages have identical data access sequences. Therefore, the address generator can be very easily implemented using the IDT7381/83, as compared with the in-place scheme where more complex logic is required to generate the addresses. On the other hand, from Figure 2 it is obvious that in each stage of computation the output data is not in the same order as the input data. For example, in the first stage the first and second inputs $x(0)$ and $x(1)$ will go to the first and fifth locations after the butterfly operation. Therefore, two separate buffers are needed to temporarily store the input and output data in each stage computation.

A conventional implementation of the input and output buffers uses two sets of dual-port SRAMs as illustrated in Figure 3. Suppose the input data is already loaded into Buffer 1. Then, in the first stage of computation the butterfly unit takes data from Buffer 1 and then loads the results into Buffer 2. In the second stage of computation the butterfly unit takes data from Buffer 2 and then loads the results into Buffer 1, and so on. To switch between these two buffers, external logic such as multiplexers and tri-state buffers are necessary as shown in Figure 3. These devices not only occupy board space but also introduce extra delay in the data path thus, decreasing the system performance. It must be noted that C, D, G, H, and e^{jW} in Figure 3 are all complex numbers. Therefore, physically two groups of memories and buses

are needed to store and transmit the real part and the imaginary part separately.

The IDT7052 FourPort SRAM provides a much simpler and more efficient way to implement the input and output buffers as shown in Figure 4. In this implementation, the input buffer and output buffer are merged into a single memory space. Since each of the four ports can access the whole memory space, two of them can be dedicated to sending the data C and D to the butterfly unit and the other two can be dedicated to receiving the results G and H from the butterfly unit. In this way, all external logic can be eliminated and the system performance is greatly improved.

Using the IDT7052 in a Matrix Multiplication Engine for Graphics and DSP

Matrix multiplication is one of the most often used operations in DSP algorithms. In addition, matrix multiplication is the basic operation at the heart of computer graphics. For example, changing the position, orientation, and size of objects in a drawing requires a geoetrical transformation **M** which is generally represented by a series of matrix multiplications.

$$M = M_1 \cdot M_2 \cdot M_3 \cdot ...... \cdot M_n \qquad (2\text{-}1)$$

Initial Address and Controls

Figure 5. Implementation of Matrix Multiplication Engine Using Standard SRAMs

where **M1** is a scaling, translation, or rotation matrix.

In high performance systems, a matrix multiplication engine (MME) is necessary to facilitate the operation. A typical pipelined MME has the architecture shown in Figure 5 [2]. Since the MME operates in a pipelined manner, three standard SRAMs (IDT6116 2Kx8 SRAMs) are needed to store the multiplicand matrix **A**, multiplier matrix **B**, and the product matrix **C** = **A•B**. The matrices **A** and **B** are preloaded into the two SRAMs from the main memory or a peripheral. The MME then performs the matrix multiplica-tion and loads the product matrix **C** into the third SRAM. Finally, the multiplication result is sent back to the main

memory or the peripheral. This implementation has two drawbacks:

1. Three separate sets of SRAMs are needed. This results in a high chip count and a complicated interface to the system bus.
2. The arithmetic unit (IDT7210) of the MME is sitting idle when the data is transferred between the memory buffers and the system main memory. This dramatically decreases the system performance especially when the MME executes a series of matrix multiplications as given in (2-1).

Now, with the advent of the IDT7052, system designers can con-siderably improve the performance of the MME by using the FourPort
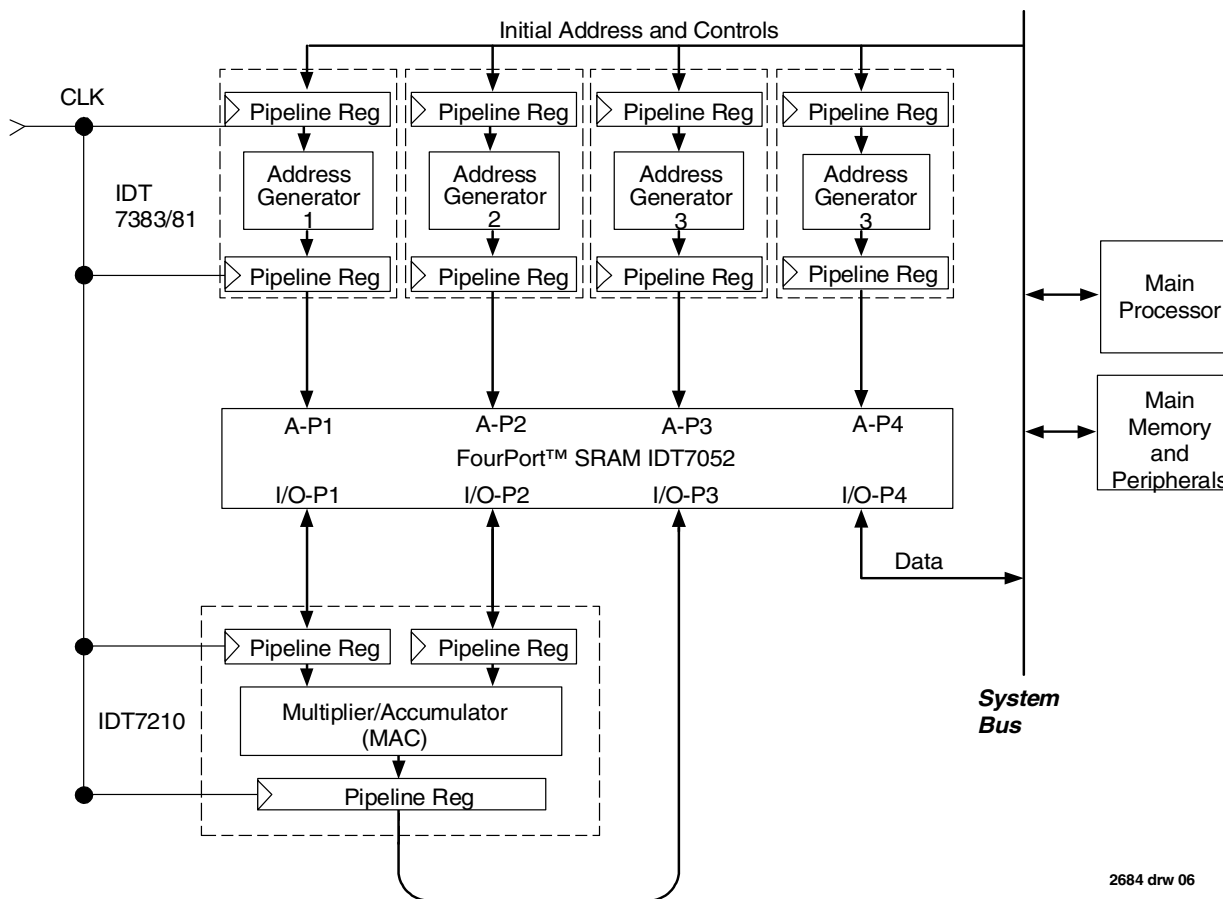

Figure 6. New Implementation of Matrix Multiplication Engine Using The IDT7052 FourPort SRAM

single-chip SRAM instead of the standard SRAM. As shown in Figure 6, the new implementation reduces the chip count and simplifies the interface between the MME and the other part of the system. Moreover, when executing a series of matrix multiplications as given in (2-1), the MME is able to perform the arithmetic operation and the data transfer in parallel, as illustrated in Figure 7. First, the matrices M_1 and M_2 are loaded into the FourPort SRAM. Then, while the arithmetic unit performs the operation $M_1 \cdot M_2$, a new matrix M_3 can be loaded into an unused area of the FourPort SRAM through the 4-th I/O port. Then, the MME will perform the multiplication $M \cdot M_3$ and the result will be stored in the location originally occupied by M_1. At the same time a new matrix M_4 can be loaded into the FourPort SRAM to replace M_2 and so on. The operation sequence of the two implementations is shown in Figure 8, where t_L is the time to load a matrix into the IDT7052, t_E is the time for the arithmetic unit to perform a matrix multiplication, and t_M is the maximum of t_L and t_E. It can be readily seen from Figure 8, where the total time to execute the operation given in (2-1) is $t_L+(n-1) \cdot (t_L+t_E)$ when conventional SRAMs are used. On the other hand, the total time is $2t_L+(n-1) \cdot t_M$ when the IDT7052 FourPort SRAM is used. If we make t_L and t_E almost equal to each other then we can almost double the system performance.

Conclusions

In this application note we have demonstrated some fundamental architectures using the IDT7052 to implement DSP and matrix algorithms. Since DSP algorithms cover a wide range of applications, there are many more architectures in which the IDT7052 FourPort SRAM can be used. The 2Kx8 FourPort SRAM and other members in the FourPort SRAM family give system designers greater opportunity and flexibility to improve system performance. The hardware designs that result tend to be far less specialized and lend themselves to new tasks with fewer hardware changes.
