

HIGH-VOLTAGE HIGH AND LOW SIDE DRIVER

- HIGH VOLTAGE RAIL UP TO 600 V
- dV/dt IMMUNITY +/- 50 V/nsec IN FULL TEMPERATURE RANGE
- DRIVER CURRENT CAPABILITY:
400 mA SOURCE,
650 mA SINK
- SWITCHING TIMES 50/30 nsec RISE/FALL
WITH 1nF LOAD
- CMOS/TTL SCHMITT TRIGGER INPUTS
WITH HYSTERESIS AND PULL DOWN
- INTERNAL BOOTSTRAP DIODE
- OUTPUTS IN PHASE WITH INPUTS

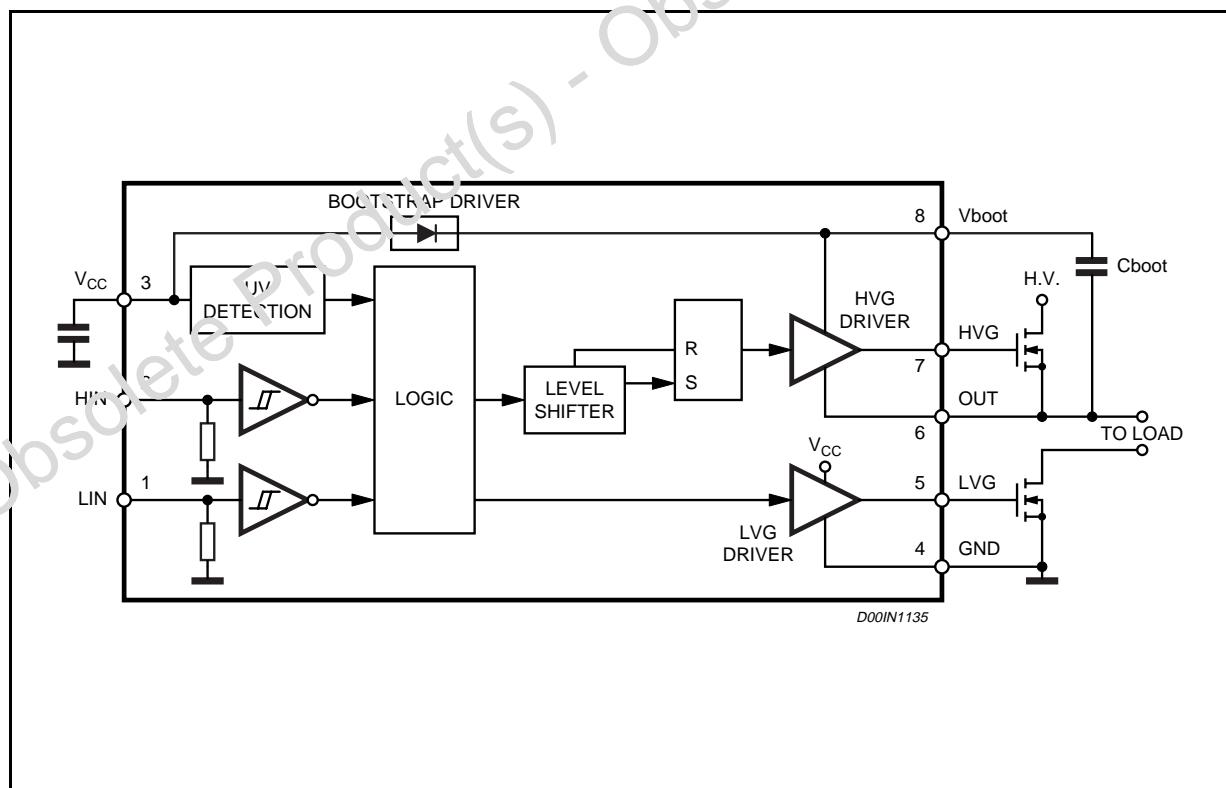

DESCRIPTION

The L6387 is an high-voltage device, manufactured with the BCD"OFF-LINE" technology. It has a Driver structure that enables to drive independent referenced N Channel Power MOS or

IGBT. The Upper (Floating) Section is enabled to work with voltage Rail up to 600V. The Logic Inputs are CMOS/TTL compatible for ease of interfacing with controlling devices.

Input Logic

L6387 Input Logic is Vcc (17V) compatible. An interlocking features is offered (see truth table below) to avoid undesired simultaneous turn ON of both Power Switches driven.

BOOTSTRAP DRIVER

A bootstrap circuitry is needed to supply the high voltage section. This function is normally accomplished by a high voltage fast recovery diode (fig. 3a). In the L6387 a patented integrated structure replaces the external diode. It is realized by a high voltage DMOS, driven synchronously with the low side driver (LVG), with in series a diode, as shown in fig. 3b

An internal charge pump (fig. 3b) provides the DMOS driving voltage .

The diode connected in series to the DMOS has been added to avoid undesirable turn on of it.

CBOOT selection and charging:

To choose the proper CBOOT value the external MOS can be seen as an equivalent capacitor. This capacitor CEXT is related to the MOS total gate charge :

$$C_{EXT} = \frac{Q_{gate}}{V_{gate}}$$

The ratio between the capacitors CEXT and CBOOT is proportional to the cyclical voltage loss .

It has to be:

$$C_{BOOT} \gg C_{EXT}$$

e.g.: if Q_{gate} is 30nC and V_{gate} is 10V, C_{EXT} is 3nF. With $C_{BOOT} = 100nF$ the drop would be 300mV.

If HVG has to be supplied for a long time, the CBOOT selection has to take into account also the leakage losses.

e.g.: HVG steady state consumption is lower than 200μA, so if HVG T_{ON} is 5ms, CBOOT has to supply 1μC to CEXT. This charge on a 1μF capacitor means a voltage drop of 1V.

The internal bootstrap driver gives great advantages: the external fast recovery diode can be avoided (it usually has great leakage current). This structure can work only if V_{OUT} is close to GND (or lower) and in the meanwhile the LVG is on. The charging time (T_{charge}) of the CBOOT is the time in which both conditions are fulfilled and it has to be long enough to charge the capacitor.

The bootstrap driver introduces a voltage drop due to the DMOS $R_{DS(on)}$ (typical value: 125 Ohm). At low frequency this drop can be neglected. Anyway increasing the frequency it must be taken in to account.

The following equation is useful to compute the

drop on the bootstrap DMOS:

$$V_{\text{drop}} = I_{\text{charge}} R_{\text{dson}} \rightarrow V_{\text{drop}} = \frac{Q_{\text{gate}}}{T_{\text{charge}}} R_{\text{dson}}$$

where Q_{gate} is the gate charge of the external power MOS, R_{dson} is the on resistance of the bootstrap DMOS, and T_{charge} is the charging time of the bootstrap capacitor.

For example: using a power MOS with a total gate charge of 30nC the drop on the bootstrap

DMOS is about 1V, if the T_{charge} is 5μs. In fact:

$$V_{\text{drop}} = \frac{30\text{nC}}{5\mu\text{s}} \cdot 125\Omega \sim 0.8\text{V}$$

V_{drop} has to be taken into account when the voltage drop on C_{BOOT} is calculated: if this drop is too high, or the circuit topology doesn't allow a sufficient charging time, an external diode can be used.
